Highlights

The Role of Continental Heterogeneity on the Evolution of Continental Plate Margin Topography at Subduction Zones

Antoniette Greta Grima, Thorsten W. Becker

- We investigate continental heterogeneity using free-surface subduction models
- Continental structure modulates OP topography, extension, trench and slab dynamics
- Variations in back-arc basin properties reflect variations in continent structure

The nature of the overriding plate plays a major role for subduction zone processes. In particular, the highly heterogeneous continental lithosphere modulates intra-plate tectonics and the surface evolution of our planet. However, the role of continental heterogeneity is relatively under-explored for the dynamics of subduction models. We investigate the influence of rheological and density variations across the overriding plate on the evolution of continental lithosphere and slab dynamics in the upper mantle. We focus on the effects of variations in continental plate margin and keel properties on deformation, topographic signals, and basin formation. Our results show that the thickness, extent, and strength of the continental plate margin and subcontinental

9 keel play a crucial role for the morphology and topography of the overriding
10 plate, as well as the retreat of the subducting slab. We show that this lateral
11 heterogeneity can directly influence the coupling between the subducting and
12 overriding plate and determine the partitioning of plate velocities across the
13 overriding plate. These findings suggest that back-arc extension and sub-
14 sidence are not solely controlled by slab dynamics but are also influenced
15 by continental plate margin and keel properties. Large extended back-arc
16 regions, such as the Pannonian and Aegean basins, may result from fast slab
17 rollback combined with a weak continental plate margin and a strong and
18 extended continental keel. Narrow margins, like the Okinawa Trough in NE
19 Japan, may indicate a comparatively stronger continental plate margin and
20 weaker or smaller continental keel. Additionally, continental keel properties
21 may affect the overall topography of the continental lithosphere, leading to
22 uplift of the deformation front and the formation of intermontane basins.

42 43 44 **1. Introduction**

45
46
47 The presence of an overriding, continental lithosphere at subduction zones
48 is a key feature of modern-day plate tectonics and exerts a first-order con-
49 trol on subduction zone evolution, trench rollback, slab dip angle at the
50 trench, and hence slab morphology on the top of the lower mantle (e.g. Cap-
51 itanio et al., 2010; Butterworth et al., 2012; Sharples et al., 2014; Holt et al.,
52

9 2015a,b; Cramer and Lithgow-Bertelloni, 2018). Relative to oceanic litho-
10 sphere, continental plates consist of thick, buoyant crust resisting recycling
11 and geologically stable regions are often underlain by strong, depleted mantle
12 lithosphere and surrounded by weak, deformable margins (e.g. Jordan, 1981;
13 Lenardic et al., 2000). Results from geopotential, seismic, tomographic, geo-
14 chemical, and rock physics studies show great variability in chemical and
15 rheological composition, thickness, temperature, density, extent, and age
16 across the continental lithosphere from its margin to its interior domains,
17 with implications for continental deformation, plate boundary weakening,
18 surface mobility and plate tectonics in general (e.g. Jordan, 1981; Ghosh
19 et al., 2010; Audet and Bürgmann, 2011; Pearson et al., 2021).

32 Continental cratons or “roots”, make up a major component of the conti-
33 nental lithosphere and these are understood to be old, thick, cold, and chem-
34 ically distinct due to their fractionation (Jordan, 1981; Lee et al., 2005). For
35 a planet with active plate tectonics, cratons are intriguing in that they have
36 resisted subduction through many Wilson Cycles. This implies continents
37 have to be neutrally or positively buoyant, and also relatively high viscos-
38 ity, to resist recycling (Lenardic et al., 2000, 2003; Rolf and Tackley, 2011;
39 Yoshida, 2012). Deeply penetrating roots underneath cratonic shields can
40 increase the coupling between the lithosphere and the mantle and modify
41 the surface deformation style (Zhong, 2001; Conrad and Lithgow-Bertelloni,
42 2006; Becker, 2006; O’Driscoll et al., 2009; Yang and Gurnis, 2016; Paul et al.,
43 2023).

9 Continental plate margins outside cratons are regions of high strain rates,
10 accommodating within their deformation most of the relative plate motions
11 (e.g. Gordon, 2000; Zhong, 2001; Becker, 2006; Ghosh et al., 2013; Yang and
12 Gurnis, 2016). At subduction zones such margins record the history of sub-
13 duction and deformation (Uyeda, 1982). Based on estimates of upper plate
14 strain derived from the type of earthquake focal mechanisms, Heuret and
15 Lallemand (2005) and Lallemand and Heuret (2017) broadly classified the
16 deformation of the overriding plate margin into either back-arc extension or
17 compression. Previous work suggests that this dichotomy of back-arc be-
18 haviour may be governed by subduction parameters, such as the convergence
19 velocity, trench rollback, the direction of motion of the overriding plate, the
20 degree of plate coupling at the trench (determined by the strength of the
21 subduction interface), the subducting plate age and the angle of subduction
22 (Sleep and Toksöz, 1971; Chase, 1978; Molnar and Atwater, 1978; Heuret
23 et al., 2007; Sdrolias and Müller, 2006; Sternai et al., 2014; Sharples et al.,
24 2014).

42
43 Significant numerical and analogue modelling efforts have sought to bet-
44 ter understand the role of the continental lithosphere at subduction zones.
45 The problem can be approached from a global, mantle flow perspective (e.g.
46 Naliboff et al., 2009; Ghosh et al., 2013; Yang and Gurnis, 2016; Paul et al.,
47 2023), or with a regional perspective which makes it easier to capture the
48 temporal evolution of the margin with high resolution (e.g. Capitanio et al.,
49 2010; Butterworth et al., 2012; Sharples et al., 2014; Holt et al., 2015a,b;

9 Cramer and Lithgow-Bertelloni, 2018; Wolf and Huisman, 2019).

10
11 Here, we build on the efforts of O’Driscoll et al. (2009), Manea et al.
12 (2012), and Taramón et al. (2015) to investigate the impact of weak conti-
13 nental margins and strong cratons on subduction dynamics. Specifically, we
14 explore the effects of variations in continental plate margin and keel prop-
15 erties on the evolution of deformation, topographic signal, and basin forma-
16 tion in a 2-D numerical model of subduction with and without a free surface
17 boundary condition. Expanding on the back-arc deformation studies for a
18 homogeneous overriding plate by Balázs et al. (2017), Wolf and Huisman
19 (2019), Dasgupta et al. (2021), and Erdős et al. (2022) we show that continen-
20 tal deformation and back-arc extension can occur in both wide and narrow
21 continental back-arcs, and is controlled to a large extent by the thickness,
22 extent, and strength of the continental plate margin and the continental keel.
23 The nature of this heterogeneity influences the extent, asymmetry of defor-
24 mation and subsidence within the back-arc region, and the amount of trench
25 retreat on the subducting plate.

44 **2. Methods**

45 *2.1. Modelling approach*

46
47 We model freely evolving subduction and interactions with an overrid-
48 ing plate within the approximation of a thermo-mechanical, 2-D convective
49 system (Holt et al., 2015a; Holt and Condit, 2021). For this, we use the fi-
50 nite element code ASPECT (version 2.3.0) (Kronbichler et al., 2012; Heister
51
52

et al., 2017; Bangerth et al., 2021) to solve the equations for the conservation of mass (eq. 1), momentum (eq. 2) and energy (eq. 3) for incompressible, laminar flow, with Boussinesq approximation and no internal heating:

$$\nabla \cdot \mathbf{v} = 0 \quad (1)$$

$$-\nabla \cdot (2\eta\dot{\epsilon}) + \nabla p = \rho\mathbf{g} \quad (2)$$

$$\left(\frac{\partial T}{\partial t} + \mathbf{v} \cdot \nabla T \right) - \kappa \nabla^2 T = 0 \quad (3)$$

Here, v is the velocity, $\dot{\epsilon}$ is the strain-rate tensor, η viscosity, p pressure, g gravitational acceleration, ρ density, T temperature, and κ thermal diffusivity. Our basic setup builds on Holt and Condit (2021), and Table 1 provides more details on the model parameters used in this study.

2.1.1. Numerical parameters and boundary conditions

Our model domain extends 11,600 km in the x -direction and 2,900 km in the y -direction (Fig. 1). Side and bottom boundaries are free slip and our top boundary is a free surface which allows for self-consistent mesh deformation and topographic build-up with model evolution. We also include model suites with a mechanical free slip top boundary condition (bc) to compare the role of the free surface in the evolution of overriding plate topography and slab dynamics (Table A.4 and Figs. A.9-A.12). For our free surface models, we

Figure 1: a) Model set-up with a free surface top boundary condition and a continental keel with inset, b), showing a zoomed-in view of the subducting and overriding plates, the weak crustal layer, and the initial condition at the start of our models for reference-keel case 4.

advect the free surface in the direction of the surface normal (instead of that of the local vertical) to avoid mesh distortions and better mass conservation preservation of the domain. We also apply a diffusion process in order to counteract the strong mesh deformation, similar to Sandiford et al. (2021). We limit our initial maximum time step (to 200 years), the relative increase in time step (to 20), and the overall maximum time step allowed in the model (to 2,000) to encourage initial isostatic convergence to equilibrium.

We use ASPECT’s adaptive mesh refinement (AMR) to increase the resolution of our models around the subducting slab, at the top of the model domain, within the overriding continental lithosphere and around and within a 7.5 km thick weak crust which acts as an interface between the subducting and overriding plates. We do this by setting AMR to occur for finite elements with large gradients in viscosity, temperature, and composition. This allows us to obtain a resolution of 500 m to 1 km within the regions of interest while also modelling flow at the scale of the whole mantle. For models

1
2
3
4
5
6
7
8
9 with a free surface top boundary condition, AMR is initiated after the first
10 0.5 Myr of model evolution to avoid recurring refinement during the free
11 surface oscillations prior to its isostatic stabilisation.
12
13
14

15 16 *2.1.2. Initial conditions* 17

18 The initial set-up for our reference case model (keel-free case 1, Table A.4)
19 includes a 6,000 km long, 80 Ma old oceanic lithosphere subducting at an
20 initial subduction angle of 70° , with a slab length of 200 km, under a 2500 km
21 long, 150 km thick, 120 Ma, buoyant continental lithosphere (Table 1). Both
22 the oceanic and continental plates are bounded by ridge segments on either
23 side of the model domain and are separated by a 7.5 km thick weak crustal
24 layer (Fig. 1). This crustal layer has viscosity of 10^{20} Pa s and acts to decouple
25 the two plates where the properties of the crustal layer were discussed by Behr
26 et al. (2022).
27
28
29
30
31
32
33
34
35
36

37 To test the role of continental heterogeneity on the evolution of sub-
38 duction and topography, we compare our keel-free case 1 model with our
39 reference-keel case 2 where we implement a 75 km thick, 200 km long keel
40 at the bottom of the continental lithosphere (Fig. 1). The continental keel
41 starts at 200 km away from the edge of the continental lithosphere at the
42 trench and extends all the way under the remaining extent of the overriding
43 plate. In our models, the keel strength is represented by a viscosity increase
44 from 10^{23} Pa s (i.e., the standard viscosity of the continental lithosphere in
45 our models) to 10^{24} Pa s. The weak crustal layer, the continental overriding

plate, and the continental keel are implemented and advected as separate compositional fields, which are discussed next.

2.1.3. Temperature and density structure

The lithospheric plates in our models are based on half-space cooling for 80 Ma and 120 Ma age, respectively. The density in our models is temperature dependent and we include different reference densities for the background mantle and oceanic lithosphere, the overriding continental plate and continental keel, and the oceanic crust (Table 1). In the reference-keel cases (cases 2 and 4), the continental plate and continental keel have the same density but this is modified for some specific test cases (Table A.4). The crust and the overriding plate material have lower densities compared to the oceanic lithosphere and mantle which is to ensure a positively buoyant continental plate and to approximate the lower density of the basaltic crust similar to the approach adopted by Behr et al. (2022).

Parameter	Symbol	Units	Value

Table 1: Model parameters

2.2. Rheology

We use a composite creep law combining diffusion creep, dislocation creep, and plastic yielding (e.g. Billen and Hirth, 2005; Becker, 2006; Garel et al., 2014). For the upper mantle, we use the following creep laws:

$$\eta_{diff/disl} = A^{\frac{1}{n}} \dot{\epsilon}_{II}^{\frac{1-n}{n}} \exp \frac{E + PV}{nRT}, \quad (4)$$

Where η is the composite viscosity, A a pre-factor, $\dot{\epsilon}_{II}$ the second invariant of the strain rate tensor, n the stress exponent, R the gas constant, P the lithostatic pressure, and T temperature. Our choices of parameters (Table 1) are consistent with experimental values for olivine (e.g. Hirth and Kohlstedt, 2004). We include a $0.3^\circ\text{C km}^{-1}$ adiabatic temperature gradient for T in eq. (4), and set the diffusion and dislocation creep pre-factors to give $\eta_{diff} = \eta_{disl} = 5 \cdot 10^{20}$ Pa s at a transition strain rate of $5 \cdot 10^{-15} \text{ s}^{-1}$ and depth of 330 km (*cf.* Billen and Hirth, 2005; Becker, 2006). We increase the viscosity of the lower mantle by a factor of 20 as motivated by geoid constraints (e.g. Hager, 1984; King and Masters, 1992) and limit deformation in the lower mantle to occur only through diffusion creep.

We include quasi-plastic behavior by approximating brittle yielding at lithospheric depths, defined as

$$\eta_{yield} = \frac{\min(\tau_{yield}, 0.5\text{GPa})}{2\dot{\epsilon}_{II}}, \quad (5)$$

1
2
3
4
5
6
7
8
9 where τ_{yield} is approximated by a Coulomb friction criterion

$$\tau_{yield} = (a\sigma_n + b)\lambda. \quad (6)$$

10
11
12 Here, a is the friction coefficient (0.6), b is the cohesion (60 MPa), λ is the
13 pore fluid factor also known as the yielding pre-factor and is defined as (e.g.
14 Enns et al., 2005)

$$\lambda = 1 - \frac{P_{fluid}}{P_{rock}} \quad (7)$$

15
16 For our reference model λ has a value of 0.15 but we increase this to 0.3
17 and decrease it to 0.07 for our reduced and increased plastic yielding cases
18 respectively (Table A.4). Similar to previous work we assume that σ_n is equal
19 to the lithostatic pressure P .

20
21 The effective viscosity is then calculated as

$$\eta_{eff} = \left(\frac{1}{\eta_{diff}} + \frac{1}{\eta_{disl}} + \frac{1}{\eta_{yield}} \right)^{-1} \quad (8)$$

22
23 and is additionally bounded between an upper limit of $2.5 \cdot 10^{24}$ and a lower
24 limit of $2.5 \cdot 10^{18}$ Pa s to encourage model convergence.

25 26 27 *2.3. Model parameters and variations*

28 We compare our keel-free case 1 and our reference-keel case 2 (sec. 2.1.2)
29 against variations in continental lithosphere strength. We first include a
30 75 km weak layer at the bottom of the continental lithosphere (keel-free case 3)
31 to approximate a rheologically weaker lower continental crust. Next, for keel-

1
2
3
4
5
6
7
8
9 case 4 we combine this weaker lower continental lithosphere with a strong
10 continental keel. This set-up describes a continental plate margin with a
11 weak lower continental crust and a continental interior underlain by stronger
12 continental lithosphere. For cases 1-4 we test each set-up using a free surface
13 and a free slip top boundary condition (Table A.4).
14
15
16
17
18

19 To explore the effect of the continental keel properties on the evolution
20 of topography and slab morphology we then vary the properties of the conti-
21 nental keel by changing its thickness (cases 5 and 6), extent (case 7), density
22 (case 8), and viscosity (cases 9 and 10; Table A.4). We also vary the margin
23 properties by decreasing the keel-free margin extent (case 11), varying its
24 thickness (case 12), and changing the amount of yielding allowed (cases 13
25 and 14; Table A.4).
26
27
28
29
30
31

33

34 35 *2.4. Model analysis*

36
37 For each model we track; i), the average overriding and subducting plate
38 velocities (measured within the plate core and averaged over the length and
39 depth of the plate), ii), the convergence velocity, iii), the velocity of the
40 sinking slab and the induced return flow in the upper mantle, iv), the viscos-
41 ity, stress, strain rate, and temperature evolution, and, v), the topographic
42 evolution.
43
44
45
46
47
48
49

50 We also measure the slab dip angle θ at 175 km depth
51

$$52 \theta = \tan^{-1} \frac{\delta y}{\delta x}, \quad (9)$$

53
54
55
56
57
58

2
3
4
5
6
7
8
9 where δy is the depth measured between 175 km at the surface and the slab
10 tip if this is above 400 km depth or at 400 km depth if the slab tip has sunk
11 into the mantle transition zone. δx describes the horizontal distance between
12 the top of the slab at 175 km depth and the slab tip.
13
14

15
16
17 The velocity V_{tr} of the subducting plate at the trench is defined here as
18 the deepest point on the subducting plate located away from the ridge and
19 is described by:
20
21
22

$$23 \quad V_{tr} = \frac{V_{stokes}}{\tan \theta}, \quad (10)$$

24
25
26 where V_{stokes} is the vertical velocity of the slab measured directly from
27 the model output and θ is the slab dip angle at 175 km depth (eq. 9).
28
29

30
31 We also define a deformation extent (Δ DE) within the overriding plate.
32 This describes the keel-free margin of the continental lithosphere. For this
33 region, we track the change in horizontal extent, strain rates, and viscosity
34 from the model output. Our convergence rate is calculated based on the ve-
35 locity of the subducting lithosphere, the trench, the deformation region, and
36 the velocity of the continental craton (defined as that part of the continental
37 lithosphere overlying by the continental keel). We also track the amount of
38 trench rollback (Δ TR) for every 0.5 Myr of model time. Lastly, we qualita-
39 tively examine the slab morphology within the upper mantle and at 660 km
40 depth.

3. Results

3.1. Surface boundary conditions, topography, and dynamics

Since we seek to evaluate topography predictions, we test a range of model set-ups (Table A.4) with both a free surface and a free slip top boundary to compare the influence of the boundary condition on the slab morphology, the strain rates and the topography generated on the overriding plate (Fig. A.13 and Table A.3). In terms of deep dynamics, there is little variation in the slab angles (Table A.3) and general slab morphology irrespective of the surface boundary conditions are used (Fig. A.9 - A.12), as expected (Kaus et al., 2008).

For keel-free case 1 and keel-case 2, continental strain rates and surface topography are also comparable save for minor, small-scale features (Figs. A.13, A.9-A.10 and Table A.3). In keel-free case 1 both the free surface and free slip implementations record a topography decrease from 4.5 to 3 km in the first 30 Myrs which decreases by another 0.5 km over the next 30 Myrs, after which elevations drop by an additional 0.5 km until the model ends at 100 Myrs. The main difference between these cases is that latter shows an offset basin subsidence ranging from 3...2.5 km in the first 31 Myr which deepens to an average constant depth of 2 km. The offset basin is bound by higher elevations of 4 - 3.5 km on either side for the first 31 Myrs. By model end time at 100 Myrs, the elevation of the basin shoulders drops by an additional 0.5 km. Continental plate margin strain rates for keel-case 2 and keel-free case 1 are similar across both models and top boundary conditions

1
2
3
4
5
6
7
8
9 for the entire model run and the upper mantle stages of the slab sinking
10 (Table A.3).
11

12
13 However, when introducing vertical and lateral heterogeneity within the
14 overriding continental plate in keel-free case 3 and keel-case 4, the type of
15 surface boundary condition becomes important for surface deformation (mea-
16 sured here as a function of strain rates and basin depth and width). For these
17 cases the free surface implementation shows higher strain rates within the
18 continental lithosphere for the first 30 Myrs of model evolution (cf. Crameri
19 and Lithgow-Bertelloni, 2018) (case 3: $5.3 \cdot 10^{-16} \text{ s}^{-1}$ for free surface vs.
20 $4.2 \cdot 10^{-16} \text{ s}^{-1}$ free slip and case 4: $5.4 \cdot 10^{-16} \text{ s}^{-1}$ for free surface vs. $2.5 \cdot 10^{-16}$
21 s^{-1} free slip) and produces significantly different topographic signals com-
22 pared to the free slip version of the same set-up (Fig. A.13) with free slip.
23 In case 3 both free surface and free slip set-ups record elevations of 5 km
24 across the entire continental lithosphere for the first ~ 15 Myr. Elevation
25 decreases rapidly in the following 15 Myrs (from 5 to 3 km) and stabilise
26 around 3...2.5 km between 25...60 Myr. Continental topography continues
27 to decrease after 60 Myr to an average of 2 km for the free slip case and
28 1.5 km in the free surface case. However, in the free surface implementation,
29 the high topography (5 km) observed in the first 15 Myrs is interrupted by
30 five basins with depths ranging from 4...3.5 km. Between 17 and 47 Myrs
31 these coalesce in to two basins which are 1 km deeper than the surrounding
32 topography, and eventually merge into a 470 m wide basin that is 1 km deep
33 and bound on either side by elevations of 2 km. Basin presence is coincident

9 with higher strain rates within the continental plate margin ($5.3 \cdot 10^{-16} \text{ s}^{-1}$).
10 Both topographic behaviour and increases in strain rates are missing for the
11 same model set-up with a free slip top boundary condition (Fig. A.11 and
12 Table A.3). Case 4-free surface develops a well defined central zone of subsi-
13 dence at 6 Myr with a depth 4 km and shoulder elevations of 4.5 km. The
14 central basin topography drops with time until it reaches a depth 0.5 km
15 with basin shoulder elevation of 2 km at 100 Myrs. In this case too, basin
16 formation and subsidence mirror higher strain rates within the continental
17 overriding plate margin (Fig. A.12 and Table A.3). The free slip version
18 shows more subdued topography, indicating that while slab deep dynamics
19 are comparable, the more involved free surface treatment may be required
20 for more detailed topography analysis (Figs. A.13, A.12), and will hence be
21 adopted subsequently.

37 *3.2. Keel variations*

38
39
40 Comparing keel-free case 3 and keel-case 4 (Figs. A.11 vs. A.12) it is clear
41 that the presence of a higher viscosity continental keel underneath the con-
42 tinental interior makes an important contribution to the return flow within
43 the upper mantle, the slab morphology, the location of deformation and the
44 overall evolution of topography on the overriding plate. The keel in case 4
45 encourages strain rate focusing within the continental plate margin, result-
46 ing in a centralized zone of subsidence bounded by two shoulders of higher
47 topography on either side of the margin, mimicking “horst” and “graben”

9 structures. This topographic signal forms early on in the model and is main-
10 tained through the model evolution. However, does the nature of the lateral
11 heterogeneity introduced by the continental keel matter? To answer this
12 question we vary the geometry and the rheology of the continental keel and
13 compare the topographic signal, the strain rates within the continental plate
14 and the slab morphology.

17
18
19
20
21

22 *3.2.1. Geometry variations*

23
24
25 Increasing the continental keel thickness (case 5, Fig. 2 and Table A.4)
26 results in similar model behaviour and topographic signal. However, the
27 subsidence within the central basin of the continental plate margin for this
28 case, is both narrower (125 km vs. 130 km) and deeper (3.5 km vs. 3 km)
29 compared to that observed for case 4 (Table 2). Decreasing the continental
30 keel thickness (case 6) results in a significantly steeper slab overall ($\sim 70^\circ$
31 vs. the mean slab angle, $\sim 60^\circ$) and a reduced trench retreat (475 km vs.
32 860 km for case 4). Case 6 has no basins, limited margin subsidence of 1.5 km
33 and a continental interior elevation change of 1 km over the model evolution
34 (Fig. 2, Table 2). Maintaining a standard keel thickness and extending its
35 length in case 7 (Fig. 2) encourages slab tip flattening at 660 km depth. A
36 significant subsidence of 3.5 km within the continental plate margin results,
37 and a wide deformation front (890 km) forms. The margin deformation is
38 characterised by a central zone of extension split into 3 zones of subsidence
39 which merge into one basin averaging a subsidence of 3 -3.5 km. This zone

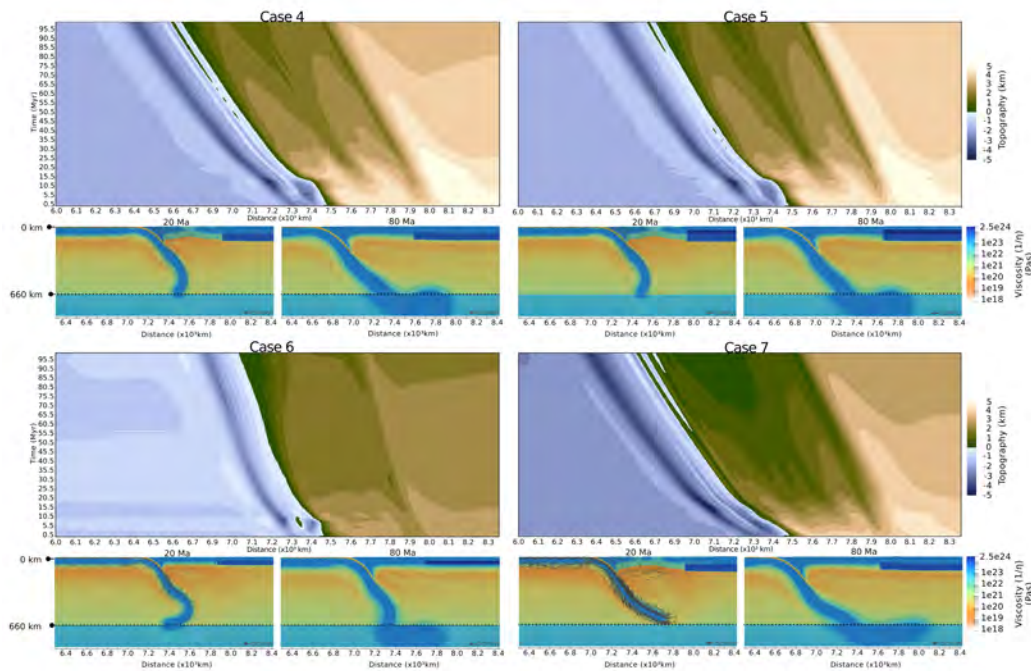

Figure 2: Effect of continental keel geometry: case 4 (top left) with standard keel; case 5 (top left) with thick keel; case 6 (bottom left) with thin keel; case 7 (bottom right) with wide keel. Layout and subplots are similar to Fig. A.13, but we now show viscosity and flow velocity at different timesteps in the small subpanels.

of extension (Table 2) is bounded by two areas with an elevation of 1 km higher than the subsided basin, similar to previous models with the same or thicker keel (cases 4 and 5).

3.2.2. Rheology variations

We next maintain the same keel geometry, but change its density in case 8 and viscosity in case 9 (Fig. 3 left and central panels and Table A.4). Introducing a continental keel with a higher density (Table A.4), results in an isostatically elevated deformed continental plate margin, with horsts that

1
2
3
4
5
6
7
8
9 are 5 km high and a subsided (1.5...1 km) continental interior. Despite the
10 inversion of the typical topographic signal between the margin and the conti-
11 nental interior we still observe a focused center of subsidence (total of 3 km)
12 within the continental plate margin. At its deepest (after a subsidence of
13 3 km) the central basin of case 8 is narrower compared to previous models
14 (150 km vs. 190 km for case 4 and 300 km for case 8) but it is similarly
15 bound by two horsts which are 1.5 km more elevated than the basin (Fig. 3
16 and Table 2).
17
18
19
20
21
22
23
24
25

26 In case 9 we maintain the reference keel density but increase its viscosity
27 by two orders of magnitude (Table A.4). The margin topography is similar to
28 that of cases 4, 5, 7, and 8 with a typical graben (with a subsidence of 3.5 km)
29 flanked by elevated horsts. Both cases 8 and 9 show similar slab behaviour
30 in the upper and lower mantle which is consistent with that observed for
31 previous cases (Fig. 3 and Table 2).
32
33
34
35
36
37

38 Lastly, in case 10 we combine the extended keel of case 7 with the higher
39 viscosity keel of case 9. We note very similar behaviour to case 7 with the
40 development of an extensive and wide deformation front (440 km) along the
41 continental plate margin. Similar to case 7, case 10 also exhibits multiple
42 basins within a central zone of subsidence along the plate margin. These are
43 the deepest basins recorded across all models with a subsidence of 4.5 km.
44 Case 10 undergoes 710 km of trench rollback which produces slab flattening
45 at 660 km depth. The slab eventually sinks below 660 km depth at 60 Myrs
46 which coincides with a secondary phase of subsidence across the two basins

9 within continental plate margin (Fig. 3).
10

11 *3.3. Margin variations*

12 *3.3.1. Geometry effects*

13
14
15 We next vary the properties of the continental plate margin. For case 11
16 (Fig. 4) we decrease the margin extent and maintain the standard keel prop-
17 erties of case 4 (Fig. 2, Table A.4). The narrower margin is more deformed
18 than in previous cases, with multiple basins evolving into 3 narrow and long
19 basins at 45 Myr. This model has the steepest slab morphology ($\sim 80^\circ$) from
20 all models for the same upper mantle stage (Table 2). Combining a thin mar-
21 gin and keel (case 12, Fig. 4) results in smooth overriding plate topography
22 where the overall elevation change across 100 Myrs of model evolution is just
23 1.5 km. Case 12 also lacks regions of uplift and basin nucleation common to
24 the previous cases. The smooth and overall shallow topography (maximum
25 topography reaches 3 km at model start and drops to 1.5 km after 76 Myr)
26 is similar to the topographic signal recorded in case 6 (Fig. 2) and both cases
27 show limited margin extent (50 km for case 12 vs. 75 km for case 6) and
28 trench rollback (580 km for case 12 and 475 km for case 6). Case 12 shows
29 transient, minor subsidence of 0.5 km along a narrow ledge between the mar-
30 gin and the continental keel, a steep slab ($\sim 74^\circ$ in the upper mantle stages
31 and 61° for the whole model run), and limited trench rollback of 580 km
32 (Table 2, Fig. 4).

8
9 *3.3.2. Rheology effects*

10
11 We next test the effect of rheology (Fig. 5). Models have a standard keel
12 but for case 13 the amount of plastic yielding allowed within the continental
13 lithosphere (excluding the keel) is reduced by changing λ from 0.15 to 0.3
14 (cf. Enns et al., 2005). In case 13, an overall high topography of 5...4.5 km
15 within the continental plate margin complements the elevated (5 km) conti-
16 nental interior for the first 15 Myrs of model evolution (Fig. 5). After 20 Ma
17 the topography within the margin flattens from 5 km to 3...1.5 km and after
18 50 Myrs multiple narrow zones of focused subsidence ~ 0.5 km deeper than
19 the surrounding topography develop. A consistent depression with a subsi-
20 dence of 2 km also develops at 1 Myr within the continental plate margin at
21 the edge of the keel shoulder (Fig. 3 and Table 2). Contrary to the subsidence
22 in previous models this is confined the keel-ward edge of the margin (Fig. 4).
23 Despite the different margin topography the slab evolution is similar to that
24 observed for cases 4, 5, 8 and 9 (Fig. 5, Table 2).
25

31
32
33
34
35
36
37
38
39
40

41 In case 14 (Fig. 5) we increase the amount of plastic yielding allowed
42 within the continental lithosphere (excluding the continental keel) by de-
43 creasing λ from 0.15 to 0.07. Increased plastic yielding results in an extended
44 continental plate margin (430 km wide) with 3.5 km of subsidence. Subsi-
45 dence is focused within two main basins which are bound by three horsts
46 which are between 0.5-1 km higher than the basins they separate and bind
47 on either side. The slab angles and morphology mimic that of cases 7 and
48 10 with deflection above 660 km and eventual descent into the lower mantle

Table 2: Subduction parameters for models with keel (cases 4-10) and margin variations (cases 11-14). *Slab angles are measured at 175 km depth using eq. 9. Note: number of basins refers to the basins at the end of the model run and interior elevations change refers to the change in elevation of the continental interior (above the continental keel) from start to end of model.

after 60 Myr (Fig. 5, Table2).

3.4. The influence of continental heterogeneity on trench retreat and the extent of continental plate margin deformation

Heterogeneity in the continental lithosphere thus influences the morphology and topography of the overriding plate, and the trench retreat of the subducting lithosphere. Keel geometry and rheology can play a role on both the extent and amplitude of the deformation experienced by the continental plate margin. Fig. 6 shows the amount of trench retreat (ΔTR) against the area of deformed and wide continental plate margin (ΔDE) for all keel variations, for the whole model evolution (top), and the upper mantle stages (bottom). There is a linear relationship between the increasing trench retreat and the increase in deformation extent along the continental plate margin (Fig. 6). Comparing model evolution across the entire model run, models

9 with keel geometry variations tend to slightly favour increases in trench re-
10 treat over increases in the width of deformation area (Fig. 6). Models with
11 keel rheology variations show slightly higher rates of increase in the width of
12 the margin deformation over the amount of trench retreat.
13
14
15
16

17 Fig. 6 shows that the keel influence on the overriding plate can be grouped
18 into three categories. Models with limited keel influence (group A - case 6) ex-
19 hibit a restricted deformation extent with limited margin width, topography
20 changes and no basin formation on the overriding plate. The models in group
21 A have limited trench retreat, and a steep slab angle and morphology in the
22 upper mantle (Table 2). Group C models (cases 7 and 10) show significant
23 trench retreat (890 km and 710 km respectively) and extensive deformation
24 widths (360 km and 440 km respectively) along the continental plate margin.
25 In group C, slabs flatten and travel horizontally at 660 km depth until they
26 avalanche into the lower mantle during the model later stages. These mod-
27 els exhibit multiple basin nucleation events and deep subsidence within the
28 continental plate margin. Most models, however, sit between these two end
29 members (Group B - cases 4, 5, 8, 9). The Group B models combine a mod-
30 est continental plate margin deformation width (130 km, 125 km, 310 km,
31 320 km respectively) with modest to high trench rollback (860 km, 790 km,
32 760 km, 725 km respectively). These models undergo temporary slab anchor-
33 ing at 660 km depth without the extensive flattening observed for Group C
34 models. A central basin, flanked by two zones of higher topography, is also
35 distinctive of group B models and is reminiscent of horst and graben struc-

10 margin (Table 2).

11
12
13 We observe a significant distinction between geometry and rheological
14 effects (Fig. 7). Geometry variations (cases 11 and 12) result in a spatially
15 limited deformation front (60 and 50 km respectively) and limited to modest
16 trench retreat extents (755 and 580 km respectively). However, in the case of
17 rheological heterogeneity (determined here by the amount of plastic yielding
18 allowed in the model) there is a clear trend of increasing trench retreat with a
19 widening of the deformation front on the overriding plate (Table 2), consistent
20 with the keel variations models discussed above. Models with higher plastic
21 yielding exhibit larger amounts of trench retreat and wider deformation fronts
22 on the overriding plate than those with limited plastic yielding. Higher plastic
23 yielding produces the highest amount of trench retreat (990 km) and the
24 widest deformed overriding plate margin (430 km).

34
35
36
37
38
39 Excluding models with margin geometry variations, where the continen-
40 tal plate margin deformation is dominated by the spatial limits of the margin
41 itself, the linear relationship exhibited in Figs. 6 and 7 indicates strong cou-
42 pling between the subducting plate and the weaker, more mobile continental
43 plate margin. This suggests that the overriding plate margin is being dragged
44 and extended as the slab rollback and the trench retreats. While it is clear
45 that the subducting slab drives the dynamics of the system, the structure of
46 the overriding plate controls how much of that driving force is partitioned
47 between the slab rollback and the drag of the continent towards the trench.

13
14

15
16 *3.5. The role of continental heterogeneity on strain rates and velocity parti-*
17 *tioning*
18
19

20
21 In models with continental heterogeneity subducting plate velocity in-
22 creases (ranging from 4.1 cm/yr...3.5 cm/yr) concur with periods of high
23 strain rates ($1 \cdot 10^{-15}$... $0.6 \cdot 10^{-15}$) within the continental plate margin;
24 however, for homogeneous cases the opposite is true (Fig. A.16). The same
25 trend also holds for convergence velocities for heterogeneous and homoge-
26 neous cases which suggest that that periods of higher strain rates should also
27 correspond to higher continental plate velocities (Fig. A.17). This is true for
28 the deformed, continental plate margin region; however, strain rates and the
29 continental interior velocities are anti-correlated for keel cases, and in homo-
30 geneous cases, strain rates are correlated with continental interior velocities
31 (Fig. 8).
32
33
34
35
36
37
38
39
40
41
42
43

44 This suggests that the subducting slab and continental plate margin are
45 coupled, where both move in the same direction and follow similar trends in
46 velocities (e.g. case 4 high subducting plate velocities of 4.1 cm/yr correspond
47 to high margin velocities of 2.5 cm/yr, Figs. 5, 8). Deformation is controlled
48 by the drag induced by the slab and the trench-ward mantle return flow it
49 induces on one side, pulling the weaker margins towards the trench, and the

9 stabilising influence of the continental keel (Fig. A.14, A.15). This is true
10 for all models with a continental keel but this effect is pronounced in keel-
11 case 7 and margin-case 14 (Fig. 2). In the former, the extended nature of
12 the keel results in a continental interior which is slower (0.3 cm/yr) than
13 the margin (1.6 cm/yr), while in the latter, the weaker margin accumulates
14 larger strain rates ($1 \cdot 10^{-15} \text{ s}^{-1}$) and higher velocities (2.5 cm/yr), while
15 the continental interior maintains near constant strain rates of $0.1 \cdot 10^{-15}$
16 and velocities of 0.5 cm/yr (Figs. A.15, 8d, A.18d). These trends dominate
17 during the model's first 15...20 Myrs and initiate the subsidence observed
18 in the model topography.

30 Plate velocities are also correlated with the slab dynamics in the upper
31 mantle. Fast convergence rates (e.g. cases 7 and 14, Fig. A.17a-b) are asso-
32 ciated with slab flattening at 660 km depth. Slab flattening induces stronger
33 return flow within the mantle wedge compared to other slab morphologies
34 (Figs. A.14, A.15, 2.8 cm/yr for flat slab vs. 2.2 cm/yr for standard). The
35 continental keel then forces this induced viscous flow within a narrow zone
36 underlying the continental plate margin, exerting thus an additional drag on
37 the continental plate margin in the direction of the return flow and towards
38 the trench (cf. O'Driscoll et al., 2009).

Top row: Case 2 (no keel), middle row: Case 7 (extended keel), bottom: Case 4 (standard keel) showing how for models with continental heterogeneity (keels) strain rates correlate with deformed continental plate margin velocities and are anti correlated with the continental interior velocities. The same trend is also observed for models with keels and variations in continental plate margin properties (Fig. A.18)

1
2
3
4
5
6
7
8
9 of localized strain-rates within the central axis of the margin. This strain
10 focusing allows for the nucleation of subsidence within the margin into a
11 central basin (Fig. A.15). At the surface this results in extensive trench
12 retreat (e.g. 890 km and 990 km for cases 7 and 14 respectively, Table 2)
13 and wide, extended back-arc basins (e.g. 360 km and 430 km for cases 7 and
14 14 respectively).

21 Models with thin keels and margins do not exhibit this relationship be-
22 tween the trench retreat and the continental plate margin extent. Fig. A.14c
23 shows that velocity is uniform across the thin continental plate margin and
24 the continental interior. The thin continental keel thus is ineffective at focus-
25 ing the induced mantle flow (2.3 cm/yr) into a narrow high-velocity channel
26 observed in the previous models and as a result there are no “pull-apart”
27 forces acting on the margin, and therefore no extension and a sustained and
28 defined basin presence. This indicates that the presence of a thick continen-
29 tal keel enhances and focuses the induced viscous flow in the mantle wedge
30 into a high-velocity channel directly underlying the continental plate mar-
31 gin effectively dragging the continental plate margin towards the trench (cf.
32 O’Driscoll et al., 2009; Paul et al., 2023). .

47 The continental properties thus determine how deformation is partitioned
48 across the overriding plate. Focusing of higher strain rates ($10^{-15} \dots 10^{-16} \text{ s}^{-1}$)
49 within the margin controls the width of the deformation area (increases in
50 ΔDE are proportional to increases in strain rates, cf. Fig. A.19), weakening
51 and extension experienced by the continental plate margin. This substan-

tiates the results of Wolf and Huisman (2019); we show that where plate velocities are partitioned determines the continental deformation and that continental keels play an important role in the weakening of the continental plate margin, and back-arc basin formation.

4. Discussion

4.1. Model limitations

Our models indicate that vertical and lateral rheological heterogeneity within the continental lithosphere modulates slab rollback, overriding plate deformation, back-arc basin formation, and so potentially continental extension.

In nature, the strength of the lithosphere is expected to be controlled by a range of factors, including lithological variations, evolving grain size, and other damage memory (e.g. Hirth and Kohlstedt, 2004; Montési, 2013; Bercovici and Ricard, 2016). Such effects are only approximately represented by our relatively simple rheological setup. In particular, we do not account for a reduction in plastic yield stress with progressive deformation and thus have no strain localisation. Were we to include localization, we would expect the difference in topography formation scenarios to be even more pronounced.

The rheology of our models is also simplified by excluding a multi-mineralic slab and mantle, and ignores the effects of phase changes. Moreover, mantle flow in nature is, of course, 3-D, a possibly more restrictive simplification. Work by Manea et al. (2012) and Taramón et al. (2015) shows that for 3-D

1
2
3
4
5
6
7
8
9 flat subduction the cratonic lithosphere is strongly coupled to the subducting
10 slab, enhancing further the upwards suction of the slab and closure of the
11 mantle wedge. This supports our 2-D results and suggests that in 3-D con-
12 tinental heterogeneity effects might be comparable, or perhaps locally even
13 more pronounced.
14
15
16
17
18

19 While slab dynamics, including the temporal evolution of trench retreat,
20 and the partitioning of the plate velocities may thus be affected by all of
21 these complexities, we expect the relative effects of keels on deformation to
22 be fairly similar.
23
24
25
26
27

28 *4.2. Analogues in nature*

29
30

31 Our models are not designed for specific subduction zones; instead, we
32 seek to investigate how continental heterogeneity impacts the dynamics and
33 overriding plate deformation, in general. Therefore, we can only make broad
34 comparisons between models and real world examples.
35
36
37
38
39

40 In terms of overall kinematics of plate velocities (e.g. Sdrolias and Müller,
41 2006; Capitanio et al., 2010; Faccenna et al., 2014), during major deformation
42 events, narrow margins such as Ryukyu exhibit similar overriding and sub-
43 ducting plate velocities. Such deformation behavior is found for our case 12
44 during the basin formation event, although the absolute velocities are higher
45 than for the natural case. More generally, the timing of deformation and
46 basin formation in nature is typically ~ 10 Myr (Sdrolias and Müller, 2006),
47 which is similar to the ~ 15 Myr period of high strain rates and deformation

9 our models.

10
11 We find that a combination of weak continental plate margins and strong,
12 extended keels favour wide zones of deformation (360-430 km) and extensive
13 subsidence (3.5 km). These margins exhibit multiple basins and significant
14 asymmetry reflecting the partitioning of the asthenospheric drag underneath
15 the continental plate margin. Models with wide zones of back-arc defor-
16 mation record the highest amount of trench rollback (890-990 km). This
17 behaviour is consistent with the highly extended, asymmetric back-arc de-
18 formation observed in, e.g., the Pannonian and Aegean basins (Wortel and
19 Spakman, 2000; Faccenna et al., 2014) which also record multiple basins
20 and considerable subsidence (1-4 km; Meulenkaamp et al., 1996; Horváth
21 et al., 2015). Trench rollback for the Pannonian basin is estimated to be
22 ~ 450 km and the amount of extensional deformation for the Aegean basin
23 is $\sim 400 \dots 500$ km with some remaining debate (e.g. Faccenna et al., 2014).
24 This is broadly consistent with Mediterranean back-arcs being affected by a
25 mix of rheologically variable lithosphere, contributing to the rollback driven
26 extension of the continental plate margin.

45 The properties of the continental keel can also contribute to the uplift
46 of the continental plate margin. In case 8 (Fig. 6), a denser than reference
47 keel produces a neutrally buoyant continental lithosphere and an isostati-
48 cally uplifted continental plate margin. The overall uplift signal is recorded
49 within a relatively narrow back-arc region similar to that of cases 4, 5, and
50 9 (Fig. 6). The uplifted margin in case 8 also records a central, and nar-

9 row basin suggesting an analogy to the Andean intermontane basins (e.g.
10 Horton, 2005). Although the latter are significantly shallower than the cen-
11 tral basin in case 8 (0.8 km vs. 3 km), they both show similar structural
12 features, i.e., both basins occur within elevated domains, for case 8 this is
13 the isostatically elevated margin (5 km high elevations) and in the Andean
14 intermontane basins case, this is the ~ 4 km high central Eastern Cordillera
15 (Horton, 2005).
16
17
18
19
20
21
22

23
24 Similar aspects of the tectonics can also be found within the late Creta-
25 ceous to early Paleogene intermontane basins of the Laramide in the Basin
26 and Range area, and around the Colorado Plateau (e.g. Lawton, 2019). In
27 this case, the continental lithosphere was likely strongly modified by the flat
28 slab episode, leading to hydration and/or removal of mantle lithosphere and
29 hence lateral viscosity contrasts similar to our models, although the gravi-
30 tational potential energy distributions and overall setting are different from
31 our simple subduction models.

40
41 Comparing kinematics for the Andean subduction case, fast subducting
42 slab and slow overriding plate velocities are found during periods of basin
43 formation (Sdrolas and Müller, 2006; Capitanio et al., 2010), and we observe
44 a similar but more subdued trend for case 8 during its period of high strain
45 rates and basin formation.

5. Conclusions

The structure of the overriding continental plate directly influences the evolution of topography and deformation within the continental plate margin. Variations in keel and margin properties also modulate the slab behaviour, the amount of trench retreat, and the partitioning of the slab-induced flow across the continental plate margin and between the margin and the continental interior.

Wide zones of deformation and extensive subsidence form within the back-arc region when the continental keel is strong and extended, and the margins are weak. Thin, spatially limited keels, and strong margins produce narrow back-arc margins. In nature, back-arc extension and subsidence may thus not only reflect convergence kinematics and local structure, but may also be affected by the adjacent continental lithosphere.

Large extended back-arc regions such as the Pannonian and the Aegean back-arcs may be a result of an interplay between fast slab rollback and a weak continental plate margin combined with a strong and wide continental keel. Narrow margins such as the Okinawa trough in NE Japan may be indicative of a comparatively stronger continental plate margin and weaker and/or smaller continental keel. Continental keel properties can also influence the uplift of the deformation front and encourage the formation of intermontane basins in regions such as the Andes and within the Laramide orogeny.

Our study underscores the importance of considering heterogeneities in

the continental lithosphere, such as keel and margin properties, when investigating subduction zone dynamics. Further, integrative modeling adapted to real-world subduction systems should contribute to a more comprehensive understanding of the complex interactions between oceanic plate subduction and the highly variable continental lithosphere.

Appendix A. Appendix

Appendix A.1. The top boundary condition question - free slip or free surface?

We explore the influence of a free surface and free slip top boundary condition on the evolution of topography, continental extension, trench retreat, and slab behaviour for cases 1-4 (Table A.4). For keel-free-case 1, there is little variation between the free surface and the free slip implementations for the slab morphology both at 20 Myrs when the slab is in the upper mantle, and also at 80 Myrs when the slab has sunk into the lower mantle. Strain rates are also similar and the topography at the surface is comparable save for minor, small-scale features (Fig. A.9). For reference-keel-case 2 we maintain a similar continental lithosphere thickness but introduce a 75 km thick, higher viscosity continental keel (Table A.4) at the bottom of the continental lithosphere. We find that similar to test case 1, in test case 2 there is very little variation in the slab morphology, strain rates, or topography recorded throughout the model evolution for both the free surface and the free slip cases.

Next, in keel-free-case 3, we further explore the effects of vertical viscosity variations by introducing a viscosity reduction of an order of magnitude within the bottom 50 km of the continental lithosphere (Table A.4 and sec. 2.3). We find that for these models the nature of the top boundary condition of the model is important and can result in significant differences in strain rates and in the evolution of the continental topography for the free

surface and free slip versions Fig. A.13. Fig. A.11 clearly shows that for test case 3 the free surface implementation exhibits significant focusing of higher strain rates within the continental lithosphere for the first 30 Myrs of model evolution. This produces significant topographic contrast with multiple horst and graben-like features on the overriding plate which eventually coalesce into broader wavelength zones of higher and lower topography. These variations in topography and strain rates within the overriding plate are missing in the same model set-up with a free slip top boundary condition (Fig. A.11). However, slab behaviour across the two set-ups is similar.

In keel-case 4 we include a continental keel similar to that of case 2 and maintain a viscosity reduction similar to case 3 but limit this to the keel-free margin of the continental lithosphere (secs. A.4 and 2.3). Comparing the free

Right: Free slip boundary condition. Top row: Topography; middle row: viscosity and induced viscous flow velocity; bottom row: strain rates

surface and free slip versions of test case 4 we find that similar to test case 3 the nature of the top boundary condition plays a significant role in both the strain rates and their focusing, as well as the evolution of topography at the surface. Here too, we observe strain rate focusing within the keel-free ~ 200 km continental plate margin, leading to the development of a well-defined central basin bounded by two areas of higher topography on either side. This topographic signal is maintained through the model evolution, even as the continental overriding plate undergoes overall subsidence. The free slip version of this set-up is missing both the focusing of the higher strain rates within the continental plate margin (i.e. the keel-free space between the continental edge and the keel edge) and the formation of a central basin bounded by two shoulders of higher topography (Figs. A.12 and A.13).

Figure A.11: Surface boundary conditions for keel-free-case 3 models with continental η variations. Left: Free surface boundary condition. Right: Free slip boundary condition. Top row: Topography; middle row: viscosity and induced viscous flow velocity; bottom row: strain rates

Similar to test cases 1-3, slab morphology in test case 4 does not seem to be impacted by the type of the top boundary condition implemented.

Appendix A.2. Margin and keel properties

For this study we first test the impact of top boundary conditions on the evolution of topography and slab dynamics in cases 1-4. We then analyze the role of variations in continental keel properties (cases 4-10) and continental plate margin properties (cases 11 -14). The variations tested are detailed in Table A.4. Continental heterogeneity has a first-order impact on the margin subsidence and extent, the number of basins within the back-arc region, the elevation change within the continental interior, the trench depth, and the trench rollback described in Table 2 for each model tested.

Case 4	3	130	1	1.5	4	860	54.9	73.5	$2.1 \cdot 10^{-16}$	$5.4 \cdot 10^{-16}$
Case 4 ^b	2.75	92	N/A	1.25	4.75	850	74.2	74.2	$2.5 \cdot 10^{-16}$	$2.5 \cdot 10^{-16}$

Table A.3: Same as Table 2 but subduction parameters are now measured for models with keel variations (cases 2 and 4) with a free surface (^a) and a free slip (^b) implementations. Note: Cases 1^{a-b} and 3^b do not have a defined continental plate margin. In these cases the subsidence and interior elevation changes record the elevation changes which occur over the continental overriding plate as a whole.
